

Data Pipelines

Data pipelines, filtering, logical variables and comparison operators

Introducing the pipe

At this stage in the course, the number of functions that you are familiar with has grown dramatically. To do truly powerful things with data, you need to not just call one of these functions, but string together many of them in a thoughtful and organized manner.

An example, let's return to our work with the `penguins` dataset from last lecture. In order to calculate the mean and standard deviation of bill length across each species of penguin, we need to take the original data frame and

1. Use `group_by()` to inform R we would like to calculate summaries across levels of a categorical variable (namely, the `species` variable).
2. Use `summarise()` to calculate these summaries.

A conventional approach breaks this process into two distinct lines of code and saves the output mid-way through.

```
grouped_penguins <- group_by(penguins, species)
summarise(grouped_penguins,
           bill_length_mean = mean(bill_length_mm),
           bill_length_sd = sd(bill_length_mm))
```

```
# A tibble: 3 x 3
  species  bill_length_mean bill_length_sd
  <fct>          <dbl>          <dbl>
1 Adelie         38.8            2.66
2 Chinstrap      48.8            3.34
3 Gentoo         47.6            3.11
```

An approach that is more concise, easier to read, and generally faster to run is to compose these functions together with “the pipe”. The pipe, written `|>`, is an operator that you have access to when you load the tidyverse package. If you have two functions, `f1` and `f2`, both of which take a data frame as the first argument, you can pipe the output of `f1` directly into `f2` using.

```
f1(DF) |> f2()
```

Let’s use the pipe to rewrite the code shown above.

```
group_by(penguins, species) |>
  summarise(bill_length_mean = mean(bill_length_mm),
            bill_length_sd = sd(bill_length_mm))
```

```
# A tibble: 3 x 3
  species  bill_length_mean bill_length_sd
  <fct>          <dbl>          <dbl>
1 Adelie         38.8            2.66
2 Chinstrap      48.8            3.34
3 Gentoo         47.6            3.11
```

The first function, `group_by()`, is unchanged. However the second function, `summarise()`, is now missing its first argument, the data frame. That is because it is being *piped directly in* from the output of the first function.

While this is a fine way to use the pipe, your code is made much more readable if you format it like this:

```
penguins |>
  group_by(species) |>
  summarise(bill_length_mean = mean(bill_length_mm),
            bill_length_sd = sd(bill_length_mm))
```

```
# A tibble: 3 x 3
  species  bill_length_mean bill_length_sd
<fct>          <dbl>          <dbl>
1 Adelie         38.8             2.66
2 Chinstrap     48.8             3.34
3 Gentoo        47.6             3.11
```

For the rest of the examples given in the notes, we will stick with this formatting when using the pipe operator. This code results in the same output as the first version, but it now reads a bit like a poem: “Take the `penguins` data frame, prepare it for calculations across each species, then calculate the mean and standard deviation of bill length (across each species of penguin)”.

This poem is admittedly not particularly poetic.

Breaking the pipe

Here’s another, less poetic way to think about the pipe, as described by the above image! Most claims about data start with a *raw* data set, undergo many subsetting, aggregating, and cleaning operations, then return a *data product*. Each one of these operations can be represented by one of the turns through

the pipe. It's good practice to understand the output of each line of code by *breaking the pipe*. With regards to our previous example, we can remove the `summarise()` and just look at the output of the `group_by()` step.

```
penguins |>
  group_by(species)
```

```
# A tibble: 333 x 8
# Groups:   species [3]
  species island    bill_length_mm bill_depth_mm flipper_length_mm body_mass_g
  <fct>   <fct>         <dbl>         <dbl>         <int>         <int>
1 Adelie  Torgersen        39.1          18.7           181           3750
2 Adelie  Torgersen        39.5          17.4           186           3800
3 Adelie  Torgersen        40.3          18             195           3250
4 Adelie  Torgersen        36.7          19.3           193           3450
5 Adelie  Torgersen        39.3          20.6           190           3650
6 Adelie  Torgersen        38.9          17.8           181           3625
7 Adelie  Torgersen        39.2          19.6           195           4675
8 Adelie  Torgersen        41.1          17.6           182           3200
9 Adelie  Torgersen        38.6          21.2           191           3800
10 Adelie Torgersen        34.6          21.1           198           4400
# i 323 more rows
# i 2 more variables: sex <fct>, year <int>
```

This looks . . . exactly like the original data frame. Well, not *exactly* like it: there is now a note at the top that the data frame now has the notion of groups based on `species`. In effect, `group_by()` has taken the generic data frame and turned it into the one in the middle below: the same data frame but with rows now flagged as belonging to one group or another. When we pipe this grouped data frame into `summarise()`, `summarise()` collapses that data frame down into a single row for each group and creates a new column for each new summary statistic.

In addition to providing greater insight on each step in your data pipeline, breaking the pipe is a fantastic way to troubleshoot any errors in your pipeline. If you run just the first piece of your pipeline and it works, add the second piece and try again. Continue this process with the rest of the pieces until the error occurs. When you run into the error, the piece you just added is the guilty party.

The pipe in action

We will now look at a few examples to understand the power of such a simple piece of syntax. In doing so, we will introduce a few more `dplyr` functions that will expand your ability to perform more specific pieces of data analysis.

Our data set of choice begins with a very general focus. In 2007, Savage and West published *A qualitative, theoretical framework for understanding mammalian sleep*¹, wherein they “develop a general, quantitative theory for mammalian sleep that relates many of its fundamental parameters to metabolic rate and body size”. Characterizing the sleep patterns of *all* mammals is a broad task and their data set is correspondingly diverse. Take a look at the first ten rows of their data below.

```
# A tibble: 83 x 5
  name                sleep_total log_bodywt vore  conservation
  <chr>                <dbl>     <dbl> <chr> <chr>
1 Cheetah              12.1       10.8 carni lc
```

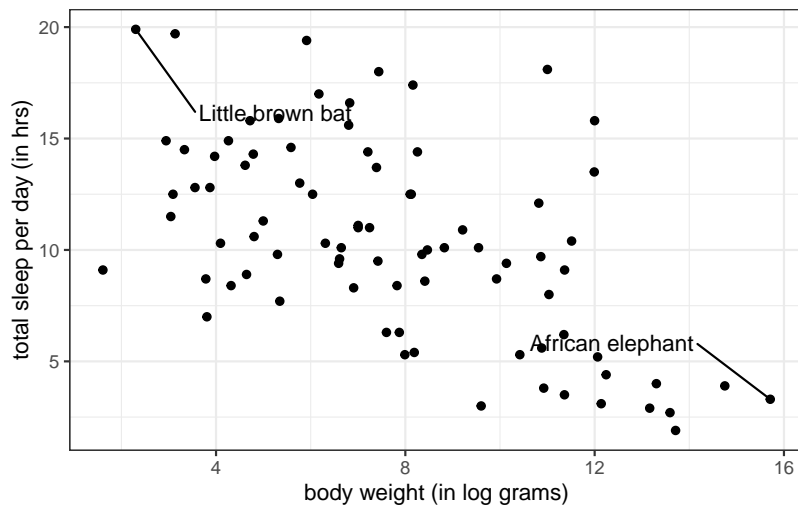

¹V. M. Savage and G. B. West. [A quantitative, theoretical framework for understanding mammalian sleep](#). Proceedings of the National Academy of Sciences, 104 (3):1051-1056, 2007.

```

2 Owl monkey          17          6.17 omni <NA>
3 Mountain beaver    14.4         7.21 herbi nt
4 Greater short-tailed shrew 14.9         2.94 omni lc
5 Cow                 4           13.3 herbi domesticated

10 Roe deer           3           9.60 herbi lc
# i 73 more rows

```

In this data set, the unit of observation is a single species and the variables observed on each are its name, the average length of sleep each day, the natural log of the average weight, its dietary pattern, and its conservation status. We can visualize the relationship between sleep and body size in all 83 species using a **scatter plot**.

The mammals vary from the wee brown bat, slumbering for nearly 20 hours a day, to the massive African elephant, nodding off for less than five. That is quite a range! Lets drill down to smaller subsets of this data frame to gain a more nuanced sense of what is going on.

Example 1: Mutation

Oftentimes the variables we are most interested in analyzing in a data set don't exist in the form most conducive for doing so. Other times, they don't exist at all. For example, note how in our first output of the `msleep` data and the scatter plot that body weight is being presented in *log grams* (`log_bodywt`). In reality, the body weight as originally present in the `msleep` dataset is called `bodywt` and is recorded in kilograms! To get to `log_bodywt`, we will perform what is called a mutation.

Mutation

The act of creating a new column in a dataset based on information in existing column(s).

There are a variety of different mutations that you can apply to a column(s) in a dataset. In the last lecture, we *overwrote* an existing column with an updated version of itself. Today, we will perform a mathematical mutation on the `bodywt` column.

```
msleep |>
  mutate(log_bodywt = log(bodywt * 1000)) |>
  select(log_bodywt, bodywt)
```

```
# A tibble: 83 x 2
  log_bodywt bodywt
  <dbl>      <dbl>
1     10.8     50
2      6.17    0.48
3      7.21    1.35
4      2.94    0.019
5     13.3    600
6      8.26    3.85
7      9.93   20.5
8      3.81    0.045
9      9.55    14
10     9.60   14.8
# i 73 more rows
```

Here, the first argument, `msleep`, is piped to the `dplyr` function `mutate()` and the second argument, `log_bodywt`, creates

a new column named `log_bodywt` by multiplying the `bodywt` column by 100 (converting kilograms to grams) and then taking the natural log. We then pipe this output into `select()` to compare the two columns.

You can use `mutate()` to create multiple columns at the same time:

```
msleep |>
  mutate(log_bodywt = log(bodywt * 1000),
         sleep_total_min = sleep_total*60) |>
  select(log_bodywt, bodywt,
         sleep_total, sleep_total_min)
```

```
# A tibble: 83 x 4
  log_bodywt bodywt sleep_total sleep_total_min
  <dbl>      <dbl>      <dbl>          <dbl>
1      10.8     50          12.1            726
2       6.17    0.48          17            1020
3       7.21    1.35          14.4            864
4       2.94    0.019         14.9            894
5      13.3    600           4             240
6       8.26    3.85          14.4            864
7       9.93   20.5           8.7            522
8       3.81    0.045          7             420
9       9.55    14           10.1            606
10      9.60   14.8           3             180
# i 73 more rows
```

If you plan to use these new columns after creating them more than once, it's best to *save them back* into the original dataset!

```
msleep <- msleep |>
  mutate(log_bodywt = log(bodywt * 1000),
         sleep_total_min = sleep_total*60)
```

Example 2: Filtering

If you think about the shape of a data frame, there are two basic ways you might go about slicing and dicing it into smaller subsets.

One way is to go at it column-by-column. The act of selecting a subset of the columns of a data frame is called, well, *selecting*. This is what we touched on briefly in the last lecture and in the previous example. When you select a column, you can do so either by its name or by its column number (or index). Selecting columns by name is more useful because their order tends to be arbitrary and might change over the course of an analysis.

The other way to go at it is row-by-row. The act of subsetting the rows of the data frame based on their row number is called *slicing*. As with columns, the order of the rows is also often arbitrary, so this is of limited use. Much more useful is *filtering*.

Filtering The act of subsetting the rows of a data frame based on the values of one or more variables to extract the observations of interest.

In the tidyverse, these functions are named `select()`, `slice()`, and `filter()`.

Filters are powerful because they comb through the values of the data frame, which is where most of the information is. The key part of any filter is the condition that you assert for the rows that are retained in your data frame. Let's set up a filter to return only the little brown bat.

```
msleep |>
  filter(name == "Little brown bat")
```

```
# A tibble: 1 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
<chr>   <chr> <chr> <chr> <chr>          <dbl>    <dbl>    <dbl> <dbl>
1 Little~ Myot~ inse~ Chir~ <NA>         19.9      2      0.2  4.1
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

Here `name == "Little brown bat"` is the condition that must be met by any row in the data set to be retained. The syntax used to set up the condition is a comparison between a column in the data frame on the left and a possible value of that column on the right.

Example 2 Detour: Comparison Operators

The filter above uses the most direct condition: it retains the rows that have a value in the `name` variable that is precisely "Little brown bat". In this case, there is only one such row. There are a range of different comparisons that can be made, though, and each has its own operator.

Operator	Translation
<code>==</code>	equal to
<code>!=</code>	not equal to
<code><</code>	less than
<code>></code>	greater than
<code><=</code>	less than or equal to
<code>>=</code>	greater than or equal to

At first, the `==` operator looks like a typo. Why doesn't we use `=`? The reason is that a single equals sign is already busy at work in R: it sets the values of arguments inside a function. Instead of assignment, we want to determine whether the thing on the left holds the same value as the thing on the right, so we use `==`. It might help you keep things straight if you read it in your head as "is exactly equal to".

Let's return only the rows with large animals, defined as those with a log body weight greater than 12.

```
msleep |>
  filter(log_bodywt > 12)
```

```
# A tibble: 9 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
<chr>    <chr> <chr> <chr> <chr>           <dbl>    <dbl>    <dbl> <dbl>
```

```

1 Cow      Bos   herbi Arti~ domesticated      4      0.7      0.667 20
2 Asian ~ Elep~ herbi Prob~ en          3.9     NA      NA     20.1
3 Horse   Equus herbi Peri~ domesticated  2.9     0.6     1     21.1
4 Donkey  Equus herbi Peri~ domesticated  3.1     0.4     NA     20.9
5 Giraffe Gira~ herbi Arti~ cd           1.9     0.4     NA     22.1
6 Pilot ~ Glob~ carni Ceta~ cd      2.7     0.1     NA     21.4
7 Africa~ Loxo~ herbi Prob~ vu       3.3     NA      NA     20.7
8 Brazil~ Tapi~ herbi Peri~ vu       4.4     1       0.9   19.6
9 Bottle~ Turs~ carni Ceta~ <NA>    5.2     NA      NA     18.8
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>

```

There were 9 such animals and you can see all of them are large.

Example 2 Detour: Logical Operators

What if you want both the little brown bat and the African elephant? What if you want both the large creatures as well as those that sleep only briefly? These are tasks that call for multiple comparisons composed together with the logical operators `&`, `|`, and `%in%`.

This filter returns the creatures who are large and who sleep little.

```

msleep |>
  filter(log_bodywt > 12 & sleep_total < 5)

```

```

# A tibble: 8 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
  <chr>    <chr> <chr> <chr> <chr>           <dbl>    <dbl>    <dbl> <dbl>
1 Cow      Bos   herbi Arti~ domesticated      4      0.7      0.667 20
2 Asian ~ Elep~ herbi Prob~ en          3.9     NA      NA     20.1
3 Horse   Equus herbi Peri~ domesticated  2.9     0.6     1     21.1
4 Donkey  Equus herbi Peri~ domesticated  3.1     0.4     NA     20.9
5 Giraffe Gira~ herbi Arti~ cd           1.9     0.4     NA     22.1
6 Pilot ~ Glob~ carni Ceta~ cd      2.7     0.1     NA     21.4
7 Africa~ Loxo~ herbi Prob~ vu       3.3     NA      NA     20.7
8 Brazil~ Tapi~ herbi Peri~ vu       4.4     1       0.9   19.6

```

```
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

This can be read as “filter the `msleep` data frame to return the rows where both the log body weight is greater than 12 and the sleep total is less than 5”. We see that there are 8 such creatures, one fewer than the data frame with only the body weight filter (bottle-nosed dolphins sleep, on average, 5.2 hrs).

Using `&` to represent “and” is common across most computer languages but you can alternatively use the somewhat more compact syntax of simply adding the second filter after a comma.

```
msleep |>
  filter(log_bodywt > 12,
         sleep_total < 5)
```

```
# A tibble: 8 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
  <chr>    <chr> <chr> <chr> <chr>          <dbl>    <dbl>    <dbl> <dbl>
1 Cow      Bos   herbi Arti~ domesticated      4        0.7      0.667  20
2 Asian ~ Elep~ herbi Prob~ en                3.9      NA      NA      20.1
3 Horse   Equus herbi Peri~ domesticated      2.9      0.6      1      21.1
4 Donkey  Equus herbi Peri~ domesticated      3.1      0.4      NA      20.9
5 Giraffe Gira~ herbi Arti~ cd                1.9      0.4      NA      22.1
6 Pilot ~ Glob~ carni Ceta~ cd                2.7      0.1      NA      21.4
7 Africa~ Loxo~ herbi Prob~ vu                3.3      NA      NA      20.7
8 Brazil~ Tapi~ herbi Peri~ vu                4.4      1        0.9     19.6
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

These two methods are equivalent.

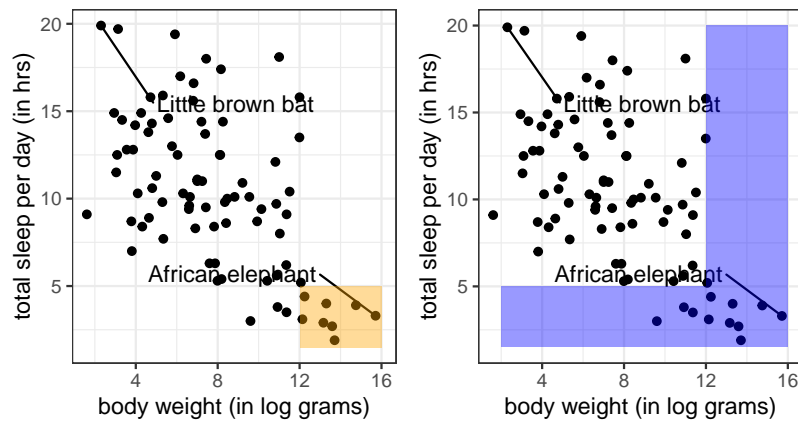

To return all rows that either have a high body weight or low sleep time or both, use the `|` operator (sometimes called “vertical bar”).

```
msleep |>
  filter(log_bodywt > 12 | sleep_total < 5)
```

```
# A tibble: 12 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
  <chr>    <chr> <chr> <chr> <chr>           <dbl>    <dbl>    <dbl> <dbl>
1 Cow      Bos   herbi Arti~ domesticated      4        0.7      0.667  20
2 Roe d~   Capr~ herbi Arti~ lc                3        NA       NA     21
3 Asian~   Elep~ herbi Prob~ en                3.9      NA       NA    20.1

11 Brazi~ Tapi~ herbi Peri~ vu                4.4      1        0.9   19.6
12 Bottl~ Turs~ carni Ceta~ <NA>                5.2      NA       NA    18.8
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

Be cautious in deciding whether you want to use `&` or `|`. While `|` is generally read as “or”, we could also describe the above filter as one that returns the rows that have a high body weight and the rows that have low sleep times.

One way to keep them straight is to keep an eye on the number of observations that are returned. The intersection of multiple conditions (using `&`) should result in the same or fewer rows (the orange area) than the union of multiple conditions (using `|`) (the blue area).

When working with nominal categorical variables, the only operator that you'll be using is `==`. You can return a union like normal using `|`,

```
msleep |>
  filter(name == "Little brown bat" | name == "African elephant")
```

```
# A tibble: 2 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
<chr>    <chr> <chr> <chr> <chr>           <dbl>    <dbl>    <dbl> <dbl>
1 Africa~ Loxo~ herbi Prob~ vu             3.3      NA      NA    20.7
2 Little~ Myot~ inse~ Chir~ <NA>          19.9     2      0.2    4.1
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

Or you can save some typing (and craft more readable code) by using `%in%` instead:

```
msleep |>
  filter(name %in% c("Little brown bat", "African elephant"))
```

```
# A tibble: 2 x 13
  name      genus vore  order conservation sleep_total sleep_rem sleep_cycle awake
<chr>    <chr> <chr> <chr> <chr>           <dbl>    <dbl>    <dbl> <dbl>
1 Africa~ Loxo~ herbi Prob~ vu             3.3      NA      NA    20.7
2 Little~ Myot~ inse~ Chir~ <NA>          19.9     2      0.2    4.1
# i 4 more variables: brainwt <dbl>, bodywt <dbl>, log_bodywt <dbl>,
#   sleep_total_min <dbl>
```

Taxonomy of Data: Logicals

It is useful to pause here to look under the hood of this code. Once you get accustomed to the comparison operators and the syntax, the R code reads very similarly to the equivalent English command. But how are those comparisons being represented in terms of data?

To answer this question, consider a simple numeric vector of four integers.

```
a <- c(2, 4, 6, 8)
```

We can apply a comparison operator to this vector using the same syntax as above. Let's compare each value in this vector to see if its less than 5.

```
a < 5
```

```
[1] TRUE TRUE FALSE FALSE
```

The result is a vector of the same length as `a` where each value indicates whether the comparison to each element was true or false. While it looks like a factor or a character vector `TRUE` and `FALSE`, this is actually our newest entry into the Taxonomy of Data: the **logical vector**.

```
class(a < 5)
```

```
[1] "logical"
```

A logical vector can only take two values, `TRUE` and `FALSE` (R also recognizes `T` and `F` but not `True` or `true`). While it might seem like a categorical variable with only two levels, a logical vector has an important property that makes it behave like a numerical variable.

```
sum(a < 5)
```

```
[1] 2
```

In a logical vector, a value of true is represented both by `TRUE` and by the number 1 and false by `FALSE` and the number 0. This integer representation is why `TRUE + TRUE` will work (it's 2!) but `"TRUE" + "TRUE"` will not.

This dual representation is very useful because it allows us to compute a proportion using, paradoxically, the `mean()` function.

```
mean(a < 5)
```

```
[1] 0.5
```

`a < 5` results in a vector with two 1s and two 0s. When you take the mean like this, you're really finding the proportion of the elements that meet the condition that you laid out in your comparison. This is a very handy trick. Let's apply it to the `msleep` dataset as part of our next example.

Example 3

In the following data pipeline, we will

1. Split our mammals up by diet (carnivore, herbivore, omnivore, etc.)
2. Calculate the proportion of mammals in each diet group that sleep over eight hours in the day
3. Calculate the number of mammals in each group

This will require both `group_by()` and `summarise()`, as well as our *handy trick* discussed above and a new summary function.

```
msleep |>
  group_by(vore) |>
  summarise(p_gt_8hrs = mean(sleep_total > 8),
            n = n())
```

```
# A tibble: 5 x 3
  vore    p_gt_8hrs     n
<chr>    <dbl> <int>
1 carni     0.684     19
2 herbi     0.594     32
3 insecti     1         5
4 omni     0.95     20
5 <NA>     0.714     7
```

- In the above code, `sleep_total > 8` creates a vector of TRUEs and FALSEs depending on whether the mammal slept for over eight hours a day. `mean()` then treats these TRUEs and FALSEs like 1s and 0s, and produces a proportion of mammals who sleep over eight hours a day in each diet group.
- The `n()` summary statistic *counts the number of observations within each group*. For example, there are nineteen carnivores in the `msleep` dataset. Based on this, we can deduce that thirteen carnivores satisfied our sleeping condition. This means that when calculating the proportion for carnivores, the `mean()` function is taking the average of thirteen 1s/TRUES and six 0s/FALSES!

The code written above could be equivalently written as follows:

```
msleep |>
  mutate(long_sleep = sleep_total > 8) |>
  group_by(vore) |>
  summarise(p_gt_8hrs = mean(long_sleep),
            n = n())
```

In this version, the `sleep_total > 8` vector is made into a new *column* using `mutate()` called `long_sleep`. This is a column of TRUEs and FALSEs, and we can then take its mean directly in the `summarise()` step.

Example 4: Arranging

Sometimes, we are interested in arranging the rows of a data frame according to some logical ordering of a column. This ordering is straightforward for numeric columns; the smallest numbers should be placed first and ascend to the larger ones (or vice versa). We might also think about what happens when passing in a column of characters. Luckily, the `dplyr` package has a catch-all solution to this in the form of the `arrange()` function.

Let's take a look:

```
msleep |>
  arrange(sleep_total) |>
  select(name, sleep_total)
```

```
# A tibble: 83 x 2
  name          sleep_total
  <chr>         <dbl>
1 Giraffe      1.9
2 Pilot whale  2.7
3 Horse        2.9
4 Roe deer     3
5 Donkey       3.1
6 African elephant 3.3
7 Caspian seal 3.5
8 Sheep        3.8
9 Asian elephant 3.9
10 Cow         4
# i 73 more rows
```

From this output, we can see that the giraffe sleeps for the smallest amount of time per day (not even two hours)! But maybe we are interested in which mammal sleeps the longest. If this is the case, we can modify the `arrange()` function slightly by wrapping our column of interest within `desc()`.

```
msleep |>
  arrange(desc(sleep_total)) |>
  select(name, sleep_total)
```

```
# A tibble: 83 x 2
  name                sleep_total
  <chr>                <dbl>
1 Little brown bat    19.9
2 Big brown bat       19.7
3 Thick-tailed opossum 19.4
4 Giant armadillo     18.1
5 North American Opossum 18
6 Long-nosed armadillo 17.4
7 Owl monkey          17
8 Arctic ground squirrel 16.6
9 Golden-mantled ground squirrel 15.9
10 Tiger              15.8
# i 73 more rows
```

What if you pass a column of characters to `arrange()`?

```
msleep |>
  arrange(vore) |>
  select(name, vore, sleep_total)
```

```
# A tibble: 83 x 3
  name                vore  sleep_total
  <chr>                <chr>    <dbl>
1 Cheetah              carni     12.1
2 Northern fur seal    carni      8.7
3 Dog                  carni     10.1
4 Long-nosed armadillo carni     17.4
5 Domestic cat         carni     12.5
6 Pilot whale          carni      2.7
7 Gray seal            carni      6.2
8 Thick-tailed opossum carni     19.4
9 Slow loris           carni      11
10 Northern grasshopper mouse carni     14.5
# i 73 more rows
```

When arranged by `vore`, `carni` comes first, and the rest of the diet groups will follow in alphabetical order. The mammals aren't arranged in any specific order within a diet group, but

we can change that by passing another column to `arrange()`. Passing additional columns to `arrange()` will systematically break ties. The below code arranges the data frame first by diet group (from A to Z) and then breaks ties by (ascending) sleep time:

```
msleep |>
  arrange(vore, sleep_total) |>
  select(name, vore, sleep_total)
```

```
# A tibble: 83 x 3
  name          vore  sleep_total
  <chr>         <chr>    <dbl>
1 Pilot whale  carni     2.7
2 Caspian seal carni     3.5
3 Bottle-nosed dolphin carni     5.2
4 Common porpoise carni     5.6
5 Gray seal    carni     6.2
6 Genet        carni     6.3
7 Northern fur seal carni     8.7
8 Red fox      carni     9.8
9 Dog          carni    10.1
10 Jaguar      carni    10.4
# i 73 more rows
```

Summary

If you're thinking, , yikes there was a *lot* of coding in these notes, you're right. Don't worry. We'll have plenty of time to practice in class! Here's a recap of what we went through.

As we begin to do analyses that require multiple operations, the **pipe operator**, `|>`, can be used to stitch the functions together into a single pipeline. With the pipe operator in tow, we then introduced some new types of data operations.

We can express existing variables in new ways or create new variables altogether by performing a **mutation**. There are several ways to subset a data frame but the most important for data analysis is **filtering**: subsetting the rows according to a

condition. In R, that condition is framed in terms of a **comparison** between a variable and a value (or set of values). Comparisons take many forms and can be combined using **logical operators**. The result is a **logical vector** that can be used for filtering or computing summary statistics. Finally, we learned to **arrange** a data frame by the ordering of a column.

The Ideas in Code

Some notes rely heavily on code to augment your learning and understanding of the main concepts. This “Ideas in Code” section is meant to expand more on concepts and functions that the notes utilize but may not fully explain.

This specific set of notes contains references to many functions from the `tidyverse` library such as `mutate()`, `select()`, `filter()`, `arrange()`, `ggplot()`, `group_by()`, `summarize()`. We delve more into some of these functions here.

`mutate()`

This function allows you to create a new column in a dataframe. In typical `tidyverse` fashion, the first argument is a dataframe. The second argument names and defines how that new column is created. Above, we saw:

```
arbuthnot %>%
  mutate(total = boys + girls) %>%
  arrange(desc(total)) %>%
  select(year, total)
```

```
# A tibble: 82 x 2
  year total
  <int> <int>
1  1705 16145
2  1707 16066
3  1698 16052
4  1708 15862
```

```
5 1697 15829
6 1702 15687
7 1701 15616
8 1703 15448
9 1706 15369
10 1699 15363
# i 72 more rows
```

Here, the first argument, `arbuthnot`, is piped to `mutate()` and the second argument, `total = boys + girls`, creates a new column named `total` by adding together the columns `boys` and `girls`. You can use `mutate()` to create multiple columns at the same time:

```
arbuthnot %>%
  mutate(total = boys + girls,
         girl_proportion = girls / total) %>%
  arrange(desc(total)) %>%
  select(year, total, girl_proportion)
```

```
# A tibble: 82 x 3
  year total girl_proportion
  <int> <int>         <dbl>
1 1705 16145         0.482
2 1707 16066         0.478
3 1698 16052         0.475
4 1708 15862         0.481
5 1697 15829         0.491
6 1702 15687         0.488
7 1701 15616         0.481
8 1703 15448         0.497
9 1706 15369         0.483
10 1699 15363         0.485
# i 72 more rows
```

Note that switching the order of the two new columns created above such that `girl_proportion = girls / total` comes before `total = boys + girls` will produce an error because `total` is used before it is created.

select()

This function is defined above as “selecting a subset of the columns of a data frame.” You’ve seen how to use `select()` to select or “grab” certain columns, but you can also use `select()` to *omit* certain columns. The last block of code can be rewritten to produce the same output by placing a minus sign, `-`, in front of the columns to omit:

```
arbuthnot %>%
  mutate(total = boys + girls,
         girl_proportion = girls / total) %>%
  arrange(desc(total)) %>%
  select(-c(boys, girls))
```

```
# A tibble: 82 x 3
  year total girl_proportion
  <int> <int>         <dbl>
1  1705 16145         0.482
2  1707 16066         0.478
3  1698 16052         0.475
4  1708 15862         0.481
5  1697 15829         0.491
6  1702 15687         0.488
7  1701 15616         0.481
8  1703 15448         0.497
9  1706 15369         0.483
10 1699 15363         0.485
# i 72 more rows
```

arrange()

This function arranges the rows of a data frame according to some logical ordering of a column. This ordering is straightforward for numeric columns; the smallest numbers are placed first and ascend to the larger ones. That is, unless you use `desc()` (which stands for descending).

But what if you pass a column of characters to `arrange()`? Let’s take a look:

```
penguins %>%
  arrange(species) %>%
  select(species, island, bill_length_mm)
```

```
# A tibble: 333 x 3
  species island    bill_length_mm
  <fct>   <fct>          <dbl>
1 Adelie Torgersen      39.1
2 Adelie Torgersen      39.5
3 Adelie Torgersen      40.3
4 Adelie Torgersen      36.7
5 Adelie Torgersen      39.3
6 Adelie Torgersen      38.9
7 Adelie Torgersen      39.2
8 Adelie Torgersen      41.1
9 Adelie Torgersen      38.6
10 Adelie Torgersen     34.6
# i 323 more rows
```

When arranged by species, Adelie penguins come first, followed by Chinstrap, then Gentoo. The penguins aren't arranged in any specific order within a species, but we can change that by passing another column to `arrange()`. Passing additional columns to `arrange()` will systematically break ties. The below code arranges the data frame first by species (alphabetically) and then breaks ties by (ascending) bill length:

```
penguins %>%
  arrange(species, bill_length_mm) %>%
  select(species, island, bill_length_mm)
```

```
# A tibble: 333 x 3
  species island    bill_length_mm
  <fct>   <fct>          <dbl>
1 Adelie Dream      32.1
2 Adelie Dream      33.1
3 Adelie Torgersen   33.5
4 Adelie Dream      34
5 Adelie Torgersen   34.4
```

```

6 Adelie Biscoe          34.5
7 Adelie Torgersen      34.6
8 Adelie Torgersen      34.6
9 Adelie Biscoe         35
10 Adelie Biscoe        35
# i 323 more rows

```

```
summarize()
```

This function summarizes a data frame into a single row. We can summarize a data frame by taking means or calculating the number of rows as above. We can also do other calculations like taking a median or calculating the variance of a column:

```

msleep %>%
  summarize(median_sleep = median(sleep_total),
            variance_sleep = var(sleep_total),
            n = n())

```

```

# A tibble: 1 x 3
  median_sleep variance_sleep     n
  <dbl>         <dbl> <int>
1      10.1         19.8    83

```

However, if `summarize()` is preceded by `group_by()`, then it will output multiple rows according to groups specified by `group_by()`:

```

msleep %>%
  group_by(vore) %>%
  summarize(median_sleep = median(sleep_total),
            variance_sleep = var(sleep_total),
            n = n())

```

```

# A tibble: 5 x 4
  vore    median_sleep variance_sleep     n
  <chr>         <dbl>         <dbl> <int>
1 carni         10.4          21.8    19
2 herbi         10.3          23.8    32

```

3 insecti	18.1	35.1	5
4 omni	9.9	8.70	20
5 <NA>	10.6	9.02	7

This syntax looks a lot like the syntax used for `mutate()`! Like in `mutate()`, we name and define new columns: `new_column = formula`. The difference is that `summarize()` returns a brand new data frame that does not contain the columns of the original data frame where `mutate()` returns a data frame with all columns of the original data frame in addition to the newly defined ones.
